## Genotypes and selection model

Given two loci, A and B, with alleles A and a, and B and b, there must be nine possible gametes. If the A allele and B allele are selected with coefficients  $s_A$  and  $s_B$ , and we assume no dominance and no epistasis, we can write the average fitness per genotype. For simplicity we use an haploid model, which would be similar to the diploid homozygotes case (also the case of highly self-fertilizing species):

	B	b
A	$[(1 + s_A)(1 + s_B)]^\epsilon$	$[(1 + s_A)(1 - s_B)]^\epsilon$
a	$[(1 - s_A)(1 + s_B)]^\epsilon$	$[(1 - s_A)(1 - s_B)]^\epsilon$

We could then expect that the observed fitness  $y$  of one of  $N$  number of haplotype of  $p$  loci is expressed as:

$$y_h = \left[ \prod_{i=1}^p (1 + s_i X_{h,i}) \right]^\epsilon$$

## The probabilistic model

We can assume the data  $y_h$  follows a Gamma distribution (typically with  $\alpha$  and  $\beta$  parameters or  $\alpha = k$  and  $\theta = 1/\beta$ ),

$$y \sim \Gamma(\alpha, \beta)$$

The first moment is:

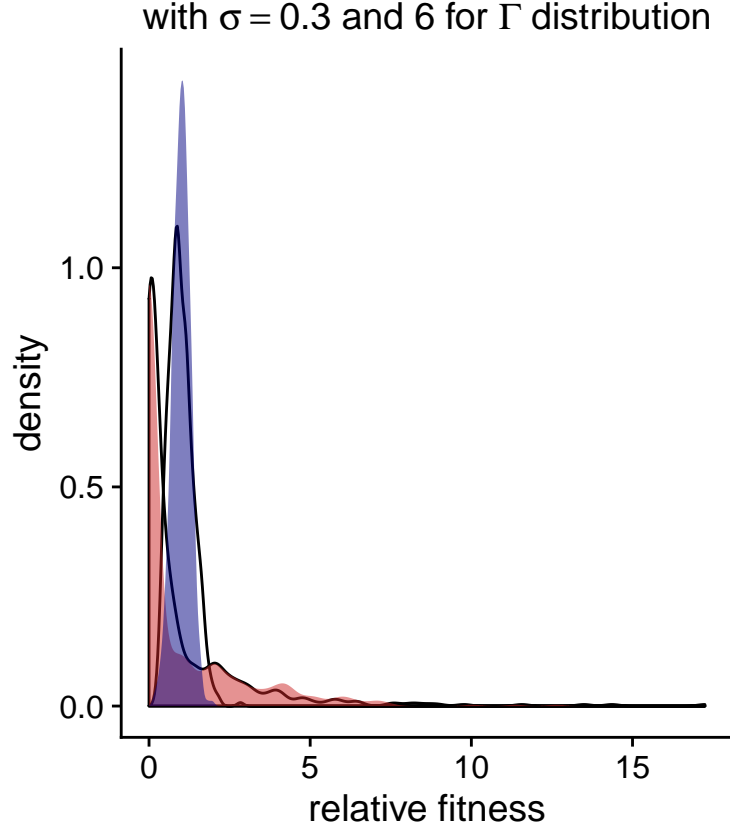

$$E[y] = \alpha/\beta = 1$$

Thus,  $\alpha = \beta$  so we use instead  $\sigma$ . This special type of  $\Gamma$  distribution will always generate a distribution whose mean is in 1, as any relative fitness situation. What contains the information is the shape of the gamma distribution, hence our use of  $\sigma$ .

The second moment is then:

$$Var(y) = \alpha/\beta^2 = \sigma^{-1}$$

In order to show that this distribution is appropriate, here are two relative fitnesses, in Madrid under drought and high water conditions. Only by moving  $\sigma$  we obtain almot perfect fit.

Then, we express  $\sigma$  in terms of selection coefficients and the epistatic term:

$$Var(y) = E[y^2] - E[y]^2 = E[y^2] = \left[ \left[ \prod_{i=1}^p (1 + s_i X_{h,i}) \right]^e \right]^2 - 1 = \prod_{i=1}^p (1 + s_i X_{h,i})^{2e} - 1 = \frac{1}{\sigma}$$

$$\sigma = \frac{1}{\prod_{i=1}^p (1 + s_i X_{h,i})^{2e} - 1}$$

The probability density function of Gamma in terms of  $k$  and  $\theta$  is:

$$f(y) = \frac{1}{\Gamma(k)\theta^k} y^{k-1} e^{-\frac{y}{\theta}}$$

In log form this can be written as:

$$\ln f(y) = (k-1) \ln(y) - \frac{y}{\theta} - \ln \Gamma(k) - k \ln \theta$$

What in terms of  $\sigma$  can be written as:

$$\ln f(y) = (\sigma-1) \ln(y) - y\sigma - \ln \Gamma(\sigma) + \sigma \ln(\sigma)$$

The derivative of this function, needed as gradient for the optimization is:

Then we can generate the full log likelihood in terms of the selection coefficients, epistatic term, and genotypes:

$$\begin{aligned}
-\ln \ell(\vec{s}, e) = & - \sum_{h \in haps.} \left[ \left( \frac{1}{\prod_{i=1}^p (1 + s_i X_{h,i})^{2e} - 1} - 1 \right) \ln(y) - \right. \\
& \frac{y}{\prod_{i=1}^p (1 + s_i X_{h,i})^{2e} - 1} \\
& \ln \Gamma \left( \frac{1}{\prod_{i=1}^p (1 + s_i X_{h,i})^{2e} - 1} \right) - \\
& \left. \frac{1}{\prod_{i=1}^p (1 + s_i X_{h,i})^{2e} - 1} \ln \left( \prod_{i=1}^p (1 + s_i X_{h,i})^{2e} - 1 \right) \right]
\end{aligned}$$

We can express this likelihood for the sake of simplicity as:

$$-\ln \ell(\vec{s}, e) = - \sum_{h \in haps.} f(y_h ; \sigma, X_h)$$

If we wanted to apply this to dense data, we can use some regularization.  $L_1 = \lambda \|w\|_1$ ,  $L_2 = \lambda \|w\|_2^2$  norms, or a combination,  $L_{12} = \lambda(m\|w\|_1 + (1-m)\|w\|_2^2)$ ,  $m \in [0, 1]$  typically used from regression approaches could be used. A plane  $L_0$  norm equal to the total number of non-zero coefficients could be adapted to the percentage of non-zero values thus  $L_0 \in [0, 1]$ , which in log would be of the same scale as the likelihood function.

$$-\ln \ell(\vec{s}, e) + \ln(L_0)$$

### Extension where $e$ is a random variable (needs to be worked out)

An important extension of this method would be to instead of estimating a common epistatic term for the whole genome, we infer its distribution.

To do that we integrate the likelihood over the distribution of  $e$  given some parameters  $\theta_e$  of such distribution with known probability density function.

$$\ln \ell(\vec{s}, \theta_e) = \int_{-\inf}^{+\inf} \sum_{h \in haps.} \ln \ell(\vec{s}, e) f(e; \theta_e) de$$

Or for feasibility, the  $e$  distribution can be binned in equal sizes and approximate:

$$\ln \ell(\vec{s}, \theta_e) \approx \sum_{m \in e \text{ bins}} \sum_{h \in haps.} \ln \ell(\vec{s}, e) P(e; \theta_e)$$

The distribution of  $e$  should be optimally a conjugate of the likelihood.
